

# DISCRIMINATION IN PROMOTION\*

Anja Prummer<sup>†</sup>

Francesco Nava<sup>‡</sup>

November 14, 2020

## Abstract

Does an employer benefit from inducing differential valuations for a promotion among his workers? In our setting, workers compete by exerting effort and higher effort corresponds to higher profit for the employer. Competition is more intense if workers have the same value distribution for the promotion. However, introducing inequalities makes workers' value more easily recognisable, reducing their information rent, which in turn increases effort. We show that if value is re-distributed, the reduction in information rent outweighs the loss in competitiveness, making discrimination between workers optimal.

*Work culture tells us what to wear, how to talk, what to talk about-in short, how to interact[...]. And yet, traditional employment anti-discrimination efforts have largely ignored the role that work culture plays in perpetuating workplace discrimination [...].*

*This is a mistake.*

Green (2005) p. 625

## 1 Introduction

The design of corporate culture as a key tool to foster worker's productivity has been identified in the business literature in the early 1980s (Ouchi and Cuchi (1981), Deal and Kennedy (1982), Peters and Waterman (1982)). It has since led employers to become increasingly concerned with a worker's *fit*<sup>1</sup>, especially at the promotion stage and in occupations, in which social relations determine success. For example, in finance, law, consulting, and academia, networking and the social relations formed are of utmost importance for individual success. At the same time, the workforce in these sectors has remained fairly homogeneous, especially at the management level, raising questions as to how employers define fit. Do employers prefer a culture that makes rising through the ranks accessible and thus appealing for all workers? Or do they instead choose to define fit more narrowly, giving some workers an advantage over others?

Our findings point towards the latter: firms prefer to induce distinct values for the promotion, which leads to differences in effort and ultimately a disparity in promotion attainment.<sup>2</sup> In our model, workers compete for a promotion by exerting effort. Their effort choices depend on their valuation for the promotion, which is private information. The employer only knows the distribution of the valuation, which is a priori identical for the workers. While workers are identical in their payoff-relevant characteristics, they differ in their label: this could be gender, race, background or simply name. The employer maximises the sum of workers' effort, their total effort, by designing an optimal mechanism and additionally, by influencing workers' value distributions for the promotion. He can influence these distributions by creating a work environment, an organisational culture that is a better fit for one worker, but ignores or disadvantages the other. His goal is to narrow distributions, making workers' values more recognisable. A recognisable value obviates incentivising the worker to reveal his value truthfully and thus the information rent vanishes. At the same time, such a value adjustment may result in reduced competition between workers. We show that as long as value is re-distributed the gain in information rent outweighs the loss in competition, increasing total effort. Even though employers do not display differences in beliefs or preferences, they still treat or reward workers distinctly, as it increases effort: discrimination is profitable.

In addition to providing a novel explanation for workplace discrimination, our model makes a contribution. By incorporating organisational culture, we allow for the employer to influence

---

<sup>1</sup>Examples of "fit" or rather of individuals not fitting in are women in an old boy's club; African Americans, who speak African American English, in a predominantly white company; black hairstyles that are ruled out in the companies dress code; a Northern accent in a London office/ a Southern accent in a New York office.

<sup>2</sup>In our setting, designing a worker's value distribution maps into designing a cost distribution.

the value distribution of workers on top of designing the optimal mechanism,. In our setting, the employer maximises total effort, the sum of effort across workers. We consider total effort as a proxy for the firm’s profit, a natural assumption in the context of finance, academia, consulting and law– all known for their competitive entry requirements, long hours and work hard mentality.

We first analyse the unconstrained maximisation problem as a benchmark, which highlights the incentives of the employer to influence distributions. The employer aims to reduce the information rent. This makes it optimal to assign all mass to one value. The employer then knows the worker’s value for the promotion exactly, leading to an information rent of zero. Given that higher values result in higher effort, the employer would like to set the value as high as possible. However, some values may be prohibitively costly, which leads us to impose an upper bound on the value for the promotion, denoted by  $\bar{\omega}$ . It is then optimal to assign mass one to  $\bar{\omega}$  for at least one worker.

Creating such a high valuation for all workers, however, may not be feasible for the employer. Supposing that the employer has limited possibilities to increase workers’ valuations, we ask whether creating a culture that affects workers differentially can be beneficial. It turns out, that this is indeed the case, which motivates the two classes of constraints, we consider: *value dispersion* and *value reallocation*.

Value dispersion focusses on value redistribution for a given worker, ignoring the other worker. This is in line with a culture, where some workers could potentially fit in, while others are immediately ruled out due to their payoff-irrelevant characteristics. The firm ignores the latter, but tailors their culture design to a specific group.

We first consider the constraint where the employer does not increase the average value for the promotion of the worker, but is otherwise unrestricted in his design. We restrict attention to this setting as we have already established that a costless increase in the expected value for the promotion will be beneficial for the employer. Eventually, such an increase in average value will no longer be costless, but the employer may still benefit from a distribution adjustment. Therefore, both workers start out with the same distribution–either because the employer has not yet influenced it or because it has been influenced in the same manner. We refer to this distribution as the initial distribution.

We show that it is optimal to adjust the initial distribution with the effort maximising distribution being binary, with mass at  $\bar{\omega}$  and zero, such that the mean of the distribution equals that of the initial distribution. The employer prefers the highest possible expected value. As this value is bounded above by the expected value of the initial distribution, the expected value of the adjusted distribution is the same as that of the original one. In order to extract the entire expected value, the employer creates a binary distribution with positive mass at exactly one positive value – reducing the information rent to zero. However, adjusting the distribution has also an impact on the effort choices of the other worker. Workers exert higher effort the greater their probability of attaining the promotion. Facing a co-worker with a high value with a high probability makes it less likely for them to receive the promotion, diminishing their effort.

Therefore, it is optimal for the employer to set the value in the adjusted distribution as high as possible as this reduces the probability for the other worker to face such a high value competitor and therefore, their effort remains high.

The binary distribution with mass at zero and the maximal value,  $\bar{\omega}$ , is optimal for the workers, if the firm can adjust the distribution for both of them – a result that may emerge if workers are affected in the same manner by the culture they face. Such an adjustment yields the same total effort as if the employer adjusted the distribution for one worker to the described, binary distribution, while using the other worker as an “insurance”: there can be a single worker whose distribution is degenerate with all mass at the average of the original distribution. If the worker with the binary distribution turns out to have zero valuation, the promotion is then given to the worker, whose valuation equals the mean, with certainty. Such an adjustment may take place if the employer can through corporate culture impose different expectations for distinct workers.

Note that the constraint of non-increasing average values encompasses a constraint that restricts the employer to adjust to distributions that are second order stochastically dominated by the original distribution. Choosing a riskier distribution is always beneficial for the firm. However, if the employer can only adjust to distributions that are first order stochastically dominated, then the employer will refrain from any adjustments. In order to make the distribution sufficiently narrow so as to make the value of the worker sufficiently precise, the employer is required to reduce the average value by so much as to make the adjustment not worthwhile.

Therefore, the employer only has an incentive to adjust values if it can make values more extreme. This implies that employers favour cultures that induce an exceedingly high valuation by a few, who become very dedicated to the job, while it alienates others. This is typical of the culture observed in law, finance, consulting or academia, in which only few thrive.

In contrast to the constraints covered by value dispersion, value reallocation allows for redistribution of value *across* workers. Organisational culture may make one worker more comfortable in a given environment, to the detriment of the other. Such an environment can arise if employers define fit around worker’s labels and they reward those that fit in, while punishing those who do not.

We assume that if the employer increases the valuation for one worker, he must decrease the valuation for the other worker by the same amount, a natural benchmark. This is equivalent to an employer who is constrained to keep the overall density of each value constant. The density of a worker’s original value distribution is denoted by  $g(v)$ , with  $v$  the value of the promotion and it is identical across workers. Therefore, the overall density for two workers at valuation  $v$  is given by  $2g(v)$  and this needs to be matched by the sum of the densities of the new distributions. As we are allowing for an arbitrary original distribution, this boils down to matching an arbitrary distribution with mass two, which we denote by  $H(v)$ . For two workers, it turns out to be optimal to create one worker whose values lie below the median of  $H(v)$  and another one, whose values are above the median of  $H(v)$ , that is to create maximally distinct value distributions

through distinct payment schedules. By creating these distinct distributions, the employer again can extract higher effort due to a reduced information rent. The employer knows more precisely, what value the worker has compared to keeping the distributions the same and thus has to leave less information rent on the table. This gain due to a reduction in information rent also offsets the reduced competition between workers. As the gain in information rent always leads to a greater increase in total effort, it is then optimal to select a culture that induces the greatest distinction between workers.

This result highlights that employers have no incentive to treat their workers equally, but rather benefit from providing advantages to one worker, to the detriment of the other.

Thus, our model introduces a novel and distinct notion of discrimination, based on corporate culture which prescribes fit. These differences do not reflect an employers' preferences or beliefs— they are distinct from taste-based discrimination (Becker (1957)) as well as statistical discrimination (Phelps (1972), Arrow (1973)). Rather, workers are treated distinctly, because it increases profits.

**Related Literature** We contribute to different strands of the literature, which we discuss in turn.

*Organisational Incentives and Culture* Our concept of discrimination relates to Winter (2004)'s discrimination among workers. There, discrimination in payment schedules emerges in order to induce workers, whose effort is complementary, to exert effort in a team moral hazard problem. In contrast, we focus on inequalities in a setting with substitutable effort induced through organisational culture. Kreps (1990) first acknowledged its importance and the desirability to incorporate corporate culture into economic theory, which has spawned a small and distinguished literature, for an overview see Hermalin (1999, 2012). The focus of this literature is how culture ensures efficient operation.<sup>3</sup> In contrast, we focus on the effects of culture on worker's valuations for a promotion: workers, who fit in more easily, find it more straightforward to obtain promotion, which corresponds to a higher valuation for it.

*Information Design* We also relate to the literature on information design in mechanisms. Condorelli and Szentes (2020), Roesler and Szentes (2017), and Bobkova (2019) focus on a buyer and seller relationship.<sup>4</sup> In these settings, the buyer (our worker) can make a costly investment or an information choice, which the seller (our employer) takes as given. In contrast, we focus on the choice of the *employer* to influence the valuation of several workers, taking into account the effect on competition, subject to a *constraint*. In the context of selling a good, this can be interpreted as designing the valuation of the good through advertisement or more directly, the design of demand functions. The latter is explicitly considered by Johnson and Myatt (2006), when selling occurs through a market. While we focus on a work environment, our results are more broadly applicable: a seller who wishes to sell a good to

---

<sup>3</sup>See Crémer (1993), Lazear (1995), Hodgson (1996) and more recently Martinez, Beaulieu, Gibbons, Pronovost, and Wang (2015), Gibbons and Kaplan (2015), Gibbons and Prusak (2020).

<sup>4</sup> Relatedly, Ali, Haghpanah, Lin, and Siegel (2020) look at designing a distribution when selling through an intermediary.

buyers through an optimal mechanism and can influence the buyers' value distributions through advertising, will choose to emphasise features of the good that lead to the valuation becoming more easily recognisable.

Contrary to our setting, the literature focuses on a buyer and seller relationship, see [Condorelli and Szentes \(2020\)](#), [Roesler and Szentes \(2017\)](#), [Bobkova \(2019\)](#). Additionally, in these settings, the buyer (our worker) can make a costly investment or an information choice, which the seller (our employer) takes as given. In contrast, we focus on the choice of the *employer* to influence the valuation, subject to a *constraint*. Moreover, we investigate the interplay between two workers and how this affects the design choices of the employer, while existing literature assumes there is only buyer.

*Inequality in Contests* Last, we contribute to the literature on inequalities in contests. [Lazear and Rosen \(1981\)](#) show that it is optimal to handicap a more able contestant. [Mealem and Nitzan \(2016\)](#) provide a survey of discrimination in contests, focusing on features of contest success functions, documenting that it is never optimal to introduce discrimination, while under some restrictive assumptions it may be beneficial to allow asymmetries to persist— in contrast to our setting, where it is optimal to *introduce* differences to a priori identical workers. Specifically, [Calsamiglia, Franke, and Rey-Biel \(2013\)](#) show in an experiment that inequalities between contestants are harmful, while affirmative action is optimal (see also [Franke \(2012\)](#)). [Li and Yu \(2012\)](#) highlights that in a contest with two unequal participants, the designer makes them equal in order to obtain the highest payoff, contrary to our finding.

The remainder of the paper is organised as follows. In Section 2, we introduce the model. We solve for the optimal mechanism and distribution subject to a constraint in Section 3. We provide a benchmark result for the optimal distribution without constraints in Section 3.1. We analyse the case of value dispersion, where we keep the average valuation weakly below the initial expected value in Section 3.2. In this context, we also characterise the optimal distribution if the employer is required to restrict attention to a distribution that is first-order and second-order stochastically dominated. We then turn to the setting in which the employer can reallocate value across workers in Section 3.3. Section 4 provides a discussion and concludes.

## 2 A Model of Discrimination in Promotion

We begin by introducing the worker's problem, before turning to the problem of the employer. The employer can influence workers' distributions of values when implementing an optimal mechanism. We first summarise classical contributions in independent private value mechanism design which constitute a key building block for our results, before focusing on the employer's problem of how to design value distributions.

## 2.1 Workers' Problem

Workers compete for a promotion by exerting effort. Every worker  $i$ , for  $i \in \{A, B\}$ , has a value for the promotion  $v_i$  which is private information and is independently distributed according to a cumulative distribution  $F_i$  with support  $V_i = [\alpha_i, \omega_i]$ . While the realisation is private, the distribution is common knowledge. In the baseline setting, workers are initially identical in their value distribution and so  $F_i = G$  for all  $i$ . Workers are faced with a direct mechanism,  $(x(\mathbf{v}), e(\mathbf{v}))$ , which for any profile of reported values  $\mathbf{v} = (v_A, v_B)$  specifies the likelihood that  $i$  gets promoted,  $x_i(\mathbf{v})$ , and the effort to exert,  $e_i(\mathbf{v})$ . Each worker maximises his expected payoff when choosing to report their valuation which ex-post amounts to

$$v_i x_i(\mathbf{v}) - e_i(\mathbf{v}). \quad (1)$$

## 2.2 Employer's Problem

The employer maximises the sum of efforts across workers, which we call *total effort*, by implementing an incentive compatible (all workers benefit by reporting their valuation truthfully) and individually rational (all workers benefit by participating) mechanism, while influencing the distribution of values for the promotion. We begin by revisiting the mechanism design problem while keeping the distribution as given, before endogenising the distributions of values.

**Classical Mechanism Design** We build on seminal results in [Myerson \(1981\)](#) to characterise total effort in the employer optimal mechanism for given value distributions. By the revelation principle, it is without loss for the employer to restrict attention to direct mechanisms in which the employer asks workers for their values and workers have an incentive to truthfully reveal these. Thus, the employer will set for all possible profiles of values  $\mathbf{v}$  an effort rule  $e(\mathbf{v})$  specifying the effort that each worker is expected to deliver and an allocation rule  $x(\mathbf{v})$  pinning down the probability of promotion for any worker. The employer sets these two rules to maximise total effort subject to incentive compatibility and individual rationality. By the revenue equivalence principle we know that the effort rule will be fully pinned down by the allocation rule if the mechanism is incentive compatible. The characterisation of the optimal mechanism is based on the *virtual valuation*, which specifies the marginal contribution of worker  $i$  with value  $v_i$  to total effort. Formally, when denoting by  $f_i$  the probability distribution for worker  $i$ , the virtual value is defined as

$$\psi_i(v_i) = v_i - \frac{1 - F_i(v_i)}{f_i(v_i)}. \quad (2)$$

Taking expectations over the virtual valuations yields the *virtual surplus*,

$$\sum_i \psi_i(v_i) x_i(\mathbf{v}). \quad (3)$$

Myerson (1981) establishes that total effort in an incentive compatible mechanism, in which the lowest type of the worker is indifferent about participating, amounts to expected virtual surplus,

$$TE(F_A, F_B) = \mathbb{E}_{\mathbf{v}} [\sum_i e_i(\mathbf{v})] = \mathbb{E}_{\mathbf{v}} [\sum_i \psi_i(v_i)x_i(\mathbf{v})]. \quad (4)$$

The optimal mechanism is therefore found by maximising expected virtual surplus subject to incentive compatibility which requires that the probability of receiving the promotion is increasing in worker's valuation; that is the virtual value is regular,  $\psi'_i(v_i) \geq 0$  for all  $i$ . If the virtual value is regular, then the optimal mechanism awards the promotion with certainty to the worker with the highest non-negative virtual valuation. However, for irregular distributions, more complicated allocation rules need to be devised to fulfil incentive compatibility.

**Quantile Space** In order to characterise the optimal mechanism when regularity fails, it is useful to move away from the traditional approach in the value – virtual value space, and to instead translate the problem to the *quantile space*, see Hartline (2013). For any distribution  $F_i$ , define the quantile associated with value  $v_i \in V_i$  as  $q_i(v_i) = 1 - F_i(v_i)$ . Similarly, define the value  $v_i(q)$  associated to any quantile  $q \in [0, 1]$  as  $v_i(q) = \sup \{v_i \in V_i | q \geq 1 - F_i(v_i)\}$ . This definition encompasses cases in which the cumulative distribution is discontinuous. If  $F_i$  is continuous and strictly increasing, we obtain  $v_i(q) = F_i^{-1}(1 - q)$ . In the quantile setting, virtual values amount to

$$\phi_i(q) = \psi_i(v_i(q)) = v_i(q) + v'_i(q)q = \frac{\partial(\Phi_i(q))}{\partial q}, \quad (5)$$

where  $\Phi_i(q) \equiv v_i(q)q$ . Further, the interim promotion probability in the quantile space is denoted by  $y_i(q) = \mathbb{E}_{\mathbf{v}_{-i}} [x_i(v_i(q), \mathbf{v}_{-i})]$  and must be non-increasing by incentive compatibility.

**Value Design Problem** Having found the optimal mechanism, conditional on the distribution, we can now focus on the employer's problem of designing the distribution. The employer can adjust the distribution of values,  $F_A$  and  $F_B$ , subject to some constraints, which capture the ability to disperse or reallocate value between workers. We assume a maximal value  $\bar{\omega} < \infty$  for the promotion. The employer's value design problem in the quantile space amounts to

$$\max_{F_A, F_B} TE(F_A, F_B) = \mathbb{E}_q [\phi_A(q)y_A(q)] + \mathbb{E}_q [\phi_B(q)y_B(q)] \quad (6)$$

s.t. constraints on distribution

Next we discuss the classes of constraints the analysis focuses on and provide some motivation. *Value Dispersion* Value dispersion focuses on the adjustment of values for a given worker, that is values can only be influenced *within* workers. As we analyse a benchmark case where the employer can adjust the distributions without any constraint, a natural second step is to assume

that the employer cannot increase the average value for the promotion. Formally,

$$\mathbb{E}_{F_i}[v] \leq \mathbb{E}_G[v], \quad (7)$$

where we index the expectation operator with the distribution  $v$  follows. Our main focus is on the case, where the employer can only adjust the distribution of one worker, keeping that of the other worker fixed. However, we also analyse the setting where the employer can adjust the distribution of both workers, without increasing the average promotion value. Constraint (7) encompasses the set of distributions that are second order stochastic dominated by the worker's initial distribution. A further obvious constraint is that of first order stochastic dominance,

$$F_i(v) \geq G(v) \text{ for all } v \in [0, \bar{w}]. \quad (8)$$

*Value Reallocation* We also consider a setting in which value can be reallocated across workers, through work cultures that lead to an increase in valuation of one worker, while decreasing the valuation of the other worker. A natural constraint is for the employer to match an arbitrary distribution  $H(v)$  which has mass two,

$$F_A(v) + F_B(v) = 2G(v) = H(v) \text{ for all } v \in [0, \bar{w}]. \quad (9)$$

**Discussion of Modelling Assumptions** We assume that both workers start out with the same distribution—either because the employer has not yet influenced it or because it has been influenced in the same manner. This serves as a benchmark to highlight that even if workers start out with the same distribution the employer has an incentive to adjust them. We allow for the employer to design the distributions freely subject to various constraints.

The first set of constraints capture an adjustment in culture, which focuses on changes in valuations within a worker, ignoring the other. This corresponds to an environment in which fitting in at the management level is only feasible for certain characteristics, which may correspond to demographics. If, for example, being a manager is associated with being male, then being a woman means to be a worse fit from the start. Sticking with the example, this implies, that the employer will focus on influencing the value distribution of the man. Assume the firm now requires men to represent a certain masculine stereotype in order for them to not only be a candidate but an actual fit. This then impacts a man's value distribution: he incurs a cost by adjusting his demeanor in order to become a fit, which reduces his value for the promotion. However, such an environment may come at a cost to women if being masculine is associated with inappropriate behaviour towards women. We aim to capture the latter by allowing for changes in values across workers. This example can easily be applied to race, with whites being a better fit than blacks and blacks incurring additional costs to become a fit; or background, with ivy league students being a better fit than those from public universities. Given how arbitrary work place culture is, with varying dress codes, appropriate ways of speaking and interacting, which are also country-specific, our modelling approach allows for a general design of valuations,

with natural and unrestrictive constraints that encompass first order and second order stochastic dominance. It turns out that the value distributions that emerge capture features of the corporate culture well, validating our approach.

### 3 Constrained Discrimination

We discuss in turn the optimal value distribution for the employer if he can disperse or reallocate value, after highlighting the optimal distribution if the employer did not face any constraints. All our proofs are collected in the Appendix.

#### 3.1 Designing Value without Constraints

Suppose the employer maximises (6) with a bounded support,  $v \in [0, \bar{w}]$  the only constraint. If so, the employer designs a value distribution such that at least one worker values the promotion at  $\bar{w}$  with certainty. Such a value design would necessarily be optimal as the employer would generate the maximal surplus, which amounts to  $\bar{w}$ , and leave no information rents to workers.

**Proposition 1.** *If the employer can adjust the value distribution for both workers, then it sets measure one to value  $\bar{w}$  for at least one worker. Formally, distribution*

$$F^{NC}(v) = \begin{cases} 0 & \text{if } v < \bar{w} \\ 1 & \text{if } v = \bar{w} \end{cases}, \quad (10)$$

*assigned to at least one worker, maximises total effort.*

This result highlights two forces at play in our model that emerge in all our results. First, the employer would like for the value of the workers to be as precise as possible, leading to an atom. Knowing precisely what the value of the worker is reduces the information rent that the employer has to pay to the worker in order to ensure incentive compatibility. To see this, note that the *information rent* in the quantile space amounts to  $v_i(q) - \phi_i(q) = v'_i(q)q$ . If the distribution consists of a single atom, the value does not change across the quantile space and therefore the information rent is reduced to zero. Therefore, creating a more narrow distribution and making the value easily recognisable, leads to a higher total effort for the employer. Second, the employer aims to increase the value for the promotion as much as possible, because a higher value induces workers to exert higher effort. Thus, the employer chooses to place all mass at the highest possible value for promotion. In the unconstrained optimal value design, it suffices to increase the value for one worker to  $\bar{w}$ , because the employer, knowing the value of that worker with certainty, is able to extract the full surplus from them without ever promoting the other worker. If the employer adjusts the distribution of both workers, then one worker obtains the promotion probability  $p \in [0, 1]$ , while the other receives it with probability  $1 - p$ . This reduces the effort of the worker, who previously obtained the promotion with certainty, while simultaneously increasing the effort of the worker, who did not receive the promotion, by the

same amount. Thus, in expectation total effort is the same, independently of whether the employer increases the value for one or both workers.

### 3.2 Value Dispersion

We now assume that the employer faces a constraint in how he can adjust the distribution. We first consider constraint (7), which imposed weakly lower means, before turning to the optimal mechanism if the new distribution is required to be first order stochastically dominated.

**Constraint: Lower Means** We keep the distribution of worker  $A$  fixed and focus on the adjustment of the value distribution of worker  $B$ , assuming that the workplace culture affects only one worker.

The optimal distribution of values for worker  $B$  allocates mass at the highest possible value of the distribution  $\bar{\omega}$  and mass at zero, such that the expected value remains unchanged, compared to the initial distribution.<sup>5</sup> This is formalised in Proposition 2, which characterises the optimal distribution.

**Proposition 2.** *Total effort is maximised among all distributions  $F$  with  $\mathbb{E}_F[v] \leq \mathbb{E}_G[v]$  by*

$$F^*(v) = \begin{cases} 1 - \frac{\mathbb{E}_G[v]}{\bar{\omega}} & \text{if } v < \bar{\omega} \\ 1 & \text{if } v = \bar{\omega} \end{cases} \quad (11)$$

To see that the expected value remains constant, note that

$$\mathbb{E}_F[v] = F^*(\bar{\omega})\bar{\omega} + (1 - F^*(\bar{\omega}))0 = F^*(\bar{\omega})\bar{\omega} = \frac{\mathbb{E}_G[v]}{\bar{\omega}}\bar{\omega} = \mathbb{E}_G[v] \quad (12)$$

The employer chooses a maximal spread of valuations for one agent. As we already demonstrated in the benchmark case, the firm would like to create as narrow a distribution as possible as this makes the worker's valuation easily identifiable. A worker's valuation is only identifiable without the firm having to pay information rent if there is mass at a single positive value. This implies that there can be mass one at the original expected value or alternatively, mass allocated to a single positive value and zero so as to match the average value of the initial distribution. At zero the firm weakly prefers to not allocate the promotion and therefore does not incentivise the worker to reveal his type. As for each of these distributions he can extract the entire valuation, the employer selects the highest possible average valuation, the expected value of the initial distribution,  $\mathbb{E}_G[v]$ . While the effort associated with each of the adjustments is the same, a change in distribution affects the probability of promotion for *both* workers.

For this reason, it is optimal to allocate a positive probability to the highest possible value instead of some other  $v < \bar{\omega}$ . Allocating positive probability to the highest positive value has an effect on worker  $A$ 's effort choice. As we keep the expected value of the distribution fixed,

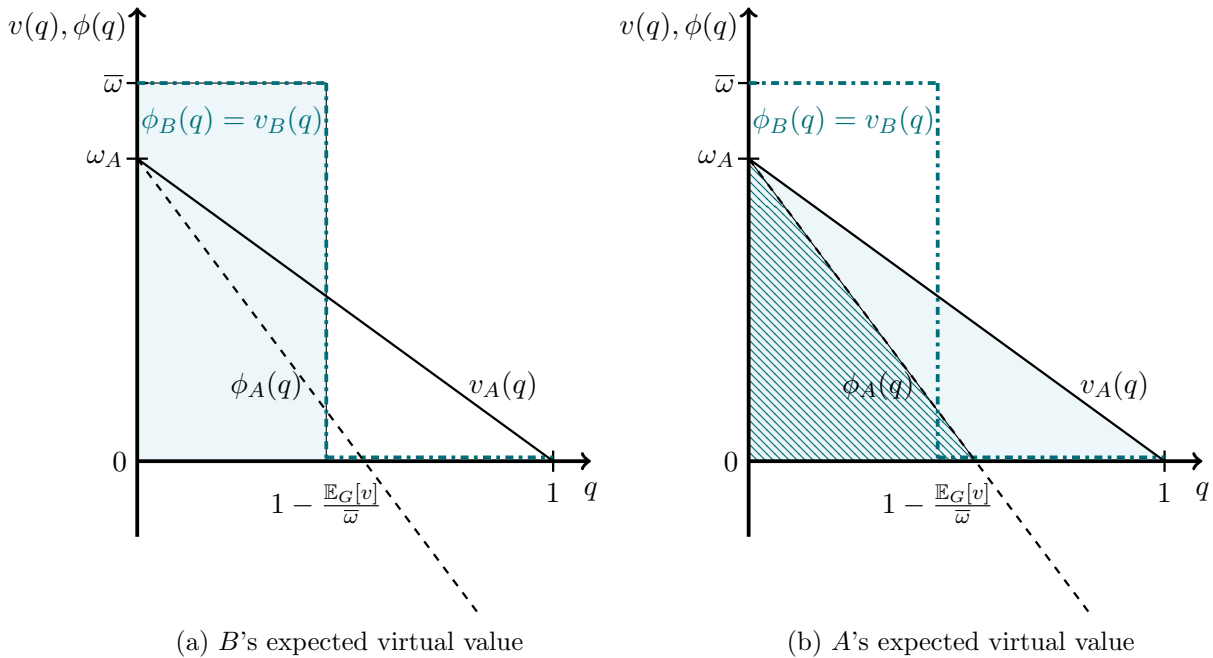

---

<sup>5</sup>This result resembles the perfect information case in information design, where the posterior jumps to either zero or one. Similarly, the constant mean translates to Bayes Plausibility, see [Kamenica and Gentzkow \(2011\)](#).

a higher value implies a lower probability that the value is positive and not zero. Therefore, a lower probability associated with  $B$ 's highest value leads to a higher probability that  $B$  has zero valuation and in turn, a higher probability for  $A$  to obtain the promotion.  $A$ 's effort decreases in  $B$ 's probability of having a high valuation and therefore it is optimal to keep this probability as low as possible – by choosing  $\bar{\omega}$ .

The intuition behind Proposition 2 is summarised graphically in Figure 1. The adjustment in distribution allows to extract the entire expected value for the promotion as the expected virtual valuation equals the expected value, see the shaded area in Figure 1a. This is more than what the employer can extract from worker  $A$ .  $A$ 's expected virtual value is depicted by the striped area in Figure 1b, which is smaller than the expected value which is given by the shaded area under  $v_A(q)$  (and which is the same size as the shaded area in 1a).

Figure 1: Value Dispersion for Worker  $B$

Note:  $B$ 's expected virtual value is depicted by the shaded area in Figure 1a, which equals  $\mathbb{E}_G[v]$ , while  $A$ 's expected virtual value is given by the striped area in Figure 1b. As the shaded area under  $v_A(q)$  equals  $\mathbb{E}_G[v]$ , it follows that  $A$ 's expected virtual value is smaller than  $B$ 's. Example assumes that  $\alpha = 0$ .

It is worth noting that Proposition 2 encompasses second order stochastic dominance, where  $B$ 's distribution is second order stochastically dominated if and only if the following holds:

$$\int_0^v G(t)dt \leq \int_0^v F_B(t)dt \quad \text{for all } v \in [0, \bar{\omega}]. \quad (13)$$

As  $F^*$  is second order stochastically dominated by  $G$ , it is also the optimal distribution among all  $F_B$  to which definition (13) applies.

**Corollary 2.1.** *Among all distributions that are second order stochastically dominated by  $G$ ,*

$F^*$  maximises total effort.

This implies that the employer always prefers a “riskier” value distribution for worker  $B$ . The result sheds light on an alternative interpretation of why the firm prefers to adjust the distribution. The employer already has a worker with a more smooth value distribution, worker  $A$ . For any realisation, worker  $A$ ’s value for the promotion is relatively similar. Therefore, the firm perceives this worker as a safety option in terms of promotion. To the contrary, worker  $B$  either has a very high or zero valuation for the promotion. If the employer discovers that  $B$  has a high valuation, then it can extract a high effort and promote worker  $B$ . The firm does make a loss if worker  $B$  turns out to have zero valuation for the promotion, but it still has worker  $A$  to fall back on.

Our results show that it is never optimal to reduce the expected valuation for the promotion. This raises the question of whether it can ever be optimal to adjust the value of a worker if this necessarily comes with a reduction in the expected value. It turns out this is indeed the case, as long as the expected value is not reduced by “too much”, which is formalised in Corollary 2.2.

**Corollary 2.2.** *For any  $m \geq \mathbb{E}_G[\max\{\psi(v), 0\}]$  the distribution*

$$F^+(v) = \begin{cases} 1 - \frac{m}{\bar{v}} & \text{if } v < \bar{v} \\ 1 & \text{if } v = \bar{v} \end{cases} \quad (14)$$

*yields higher total effort compared to no adjustment.*

The condition implies that spreading value is optimal for the employer as long as the reduction in expected value,  $\mathbb{E}_G[v] - m$ , is more than compensated by the reduction in information rent,  $\mathbb{E}_G[v] - \mathbb{E}_G[\max\{\psi(v), 0\}]$ . Thus, even if the firm loses some value for the promotion on average by adjusting the distribution, doing so still increases the total effort for the firm.

Having discussed the case where the distribution of one worker can be adjusted, we now allow for the values of both workers to be influenced, keeping expected values fixed. It is still optimal to adjust the value of one worker to the distribution described in Proposition 2. For the second worker, there are then two optimal adjustments, as summarised in Corollary 2.3.

**Corollary 2.3.** *Assume  $\mathbb{E}_{F_i}[v] \leq \mathbb{E}_G[v]$ ,  $\forall i \in \{A, B\}$ . Total effort is maximised by setting for worker  $i$ ,  $F_i^*(v) = F^*(v)$  and for worker  $j$  either (i)  $F_j^*(v) = F^*(v)$  or (ii)*

$$F_j^*(v) = \begin{cases} 0 & \text{if } v < \mathbb{E}_G[v] \\ 1 & \text{if } v \geq \mathbb{E}_G[v] \end{cases} \quad (15)$$

If the employer can adjust the distribution for both workers, he will do so. There are two possible outcomes: the employer either creates only workers, who have with a fairly small probability a very high value for the promotion. If they have a high valuation, they also exert the highest possible effort. On the other hand, with a large probability, a worker does not aim for promotion and exerts zero effort. This translates into a work environment, with few superstars that work incredibly hard and a large set of workers that simply do the basics without striving

for a promotion. Alternatively, the firm creates one value distribution which assigns a small probability to the highest value and for the other worker a distribution that assigns all mass to the expected value of the original distribution. The employer still aims to create a worker, who either exerts the highest possible effort if he turns out to have a high valuation, or zero effort, creating again a superstar environment. Such an environment comes at the cost of not having a worker with positive valuation with a high probability and thus no one to be promoted. The firm can insure against this by creating a worker, who serves as an insurance. If the worker with the stark difference in values turns out to not value the promotion, then the firm can still allocate it to the worker with the average valuation.

Interestingly, the latter adjustment yields the same total effort as creating two workers with either high or zero valuation. However, there can never be more than one worker with value at the mean, see again the proof of Proposition 2. With many workers, the firm creates an environment where all workers (potentially with the exception of one) are overachievers with a small probability.<sup>6</sup> The small probability of being an overachiever gives the illusion that once the worker has the high value, he obtains the promotion almost certainly. This allows the firm to extract high effort from all such workers, that is the firm can extract the expected value from every single worker.

**Constraint: FOSD** We keep again the value distribution of worker  $A$  fixed, and adjust the distribution of worker  $B$  such that  $A$ 's distribution first order stochastically dominates  $B$ 's distribution,  $G(v) = F_A(v_A) \leq F_B(v_B)$ . First order stochastic dominance implies a ranking of quantiles  $q_A(v)$  and  $q_B(v)$ :

$$q_B(v) = 1 - F_B(v) \leq 1 - F_A(v) = q_A(v) \quad (16)$$

It follows that for a given quantile, the value for  $A$  is higher than that for  $B$ , formally  $v_A(q) \geq v_B(q)$  for any  $q \in [0, 1]$ . This observation is summarised in Figure 2. For any distribution  $B$  that is first order stochastically dominated by a distribution  $A$ , the value of  $A$  is higher than that of  $B$  for every quantile. This allows us to work directly with the values, instead of virtual values as by integration by parts yields

$$\int_q \phi(q)y(q)dq = v(q)qy(q)\Big|_0^1 + \int_q v(q)q(-y(q))dq \quad (17)$$

This observation turns out to be instrumental in proving Proposition 3.

**Proposition 3.** *Total effort is maximised by having no discrimination and setting  $F_B^*(v) = F_A(v) = G(v)$  among all distributions  $F_B(v) \geq G(v) \forall v$ .*

If the employer can only adjust the distribution such that it is first order stochastically dominated by the original distribution, then he will never adjust the value. The firm can still make the

---

<sup>6</sup>The employer is indifferent between the  $n$ th worker having mass one at the mean or the same bimodal distribution as all the other workers.

Figure 2: A FOSD  $B$

distribution more precise, which reduces the information rent, but this comes at the cost of reducing the value for promotion dramatically. In this case, the gain in information rent never outweighs the loss in value.

To show this, we consider a distribution  $F_B(v)$  that differs from and is first order stochastically dominated by  $F_A(v)$ . This implies that there are some values for which  $B$ 's CDF is strictly above that of  $A$ . We then construct an alternative CDF for  $B$ ,  $\hat{F}_B(v)$ , which is first order stochastically dominated by  $F_A(v)$ , but first order stochastically dominates  $F_B(v)$ , again with strict inequality for some  $v$ . We show that total effort is higher under  $\hat{F}_B(v)$ . Again, a change in distribution has two effects, (i) it affects the virtual value and (ii) it affects the probability of promotion for *both* workers. To simplify our proof, we fix the allocation rule to the one that is optimal if the distribution is  $F_B(v)$  and show that the optimal total effort increases due to the adjustment of virtual values from  $F_B(v)$  to  $\hat{F}_B(v)$ . Formally, we show the second inequality in expression (18).

$$\underbrace{\mathbb{E}[\hat{\phi}_B(q)\hat{y}_B(q)]}_{\text{Distribution: } \hat{F}_B, \text{ Allocation: } \hat{F}_B} \geq \underbrace{\mathbb{E}[\hat{\phi}_B(q)y_B(q)]}_{\text{Distribution: } \hat{F}_B, \text{ Allocation: } F_B} > \underbrace{\mathbb{E}[\phi_B(q)y_B(q)]}_{\text{Distribution: } F_B, \text{ Allocation: } F_B} \quad (18)$$

The first inequality holds as total effort under the old allocation rule, associated with  $F_B(v)$ , and new virtual value derived from  $\hat{F}_B(v)$  is a lower bound on total effort, obtained from the virtual value and allocation rule associated with  $\hat{F}_B(v)$ . This follows as an adjustment of the allocation rule must increase effort – otherwise the firm would not select a new allocation rule. We then turn to a comparison of virtual values, to show that  $\mathbb{E}\left[\left(\hat{\phi}_B(q) - \phi_B(q)\right)y_B(q)\right] > 0$ . Integrating by parts leads to a comparison of values, see expression (17). We know that

distribution  $\hat{F}_B(v)$ , is associated with a higher value for each quantile compared to distribution  $F_B(v)$ , as  $\hat{F}_B(v)$  first order stochastically dominates  $F_B(v)$ , see also Figure 2. As this holds for any  $\hat{F}_B(v)$ , it follows that in optimum  $B$ 's distribution must equal  $A$ 's distribution or rather, the original distribution  $G$ .

We have shown that if the employer can influence the worker's distribution by dispersing value, he will do so, unless he is restricted to distributions which are first order stochastically dominated. In particular, he will create a bimodal distribution, which leads to workers valuing the promotion either very highly or not at all. This is in line with the environment we see in academia, law and finance: some workers value a promotion to full professor, partner, manager a lot and are willing to work incredibly hard for it. Others dislike this culture and opt out of the race, doing the minimum to keep their job. Even if such a culture comes at a cost, it can still be beneficial to implement it, as long as the cost is not too high.

### 3.3 Value Reallocation

We turn to a setting where the employer designs cultures that cater to one worker, while disadvantaging the other. A natural assumption is that an increase in valuations for one worker is compensated by a decrease in valuations for the other worker, that is value is re-allocated. This is equivalent keeping the overall density of each value constant or alternatively,  $F_A(v) + F_B(v) = 2G(v) = H(v)$ , where  $H(v)$  is an arbitrary distribution with mass *two*. If workers' distributions are identical, they are again denoted by  $G(v)$ . However, it is not optimal to create identical distributions. Rather, the employer maximises total effort by creating two maximally different value distributions. This is formalised in Proposition 4, for which it is useful to define  $v^M$  as the median of  $H(v)$ ,  $\int_{\alpha}^{v^M} dH(v) = 1$ .

**Proposition 4.** *If  $F_A(v) + F_B(v) = H(v)$ , total effort is maximised by choosing distributions*

$$F_A^*(v) = H(v) - 1 \quad \text{if } v \in [v^M, \omega], \quad (19)$$

$$F_B^*(v) = H(v) \quad \text{if } v \in [\alpha, v^M]. \quad (20)$$

Maximal discrimination, such that worker  $B$ 's values are below the median of  $H(v)$ , while worker  $A$ 's values are above the median of  $H(v)$ , always yields a higher total effort than any other two distributions. First, this adjustment narrows the distribution, by reducing the values workers can have. Additionally, it increases the probability of receiving the promotion for the worker with high values, inducing him to work harder, while lowering the probability of receiving the promotion for the low value worker. This leads to lower effort from worker  $B$ . As it turns out, the gain in information rent again outweighs the loss in competition and maximal discrimination is optimal as it minimises the information rent.

To show the optimality of maximal discrimination, we first compare maximal discrimination to any two distributions that split the densities  $h(v)$  for all  $v$  before turning to disjoint supports. These comparisons are illustrated in Figure 3, with an example of split densities illustrated in

Figure 3a. The example splits the densities in a smooth manner. However, in principle, each density can be split in an arbitrary manner. Further, we require maximal discrimination to lead to a higher total effort compared to any other distributions with disjoint support, see Figure 3b. It suffices to show that these two classes of distributions do not lead to a higher total effort compared to maximal discrimination, as any combination between split densities and disjoint support leads to a linear combination of the effort of split densities and disjoint supports– and we show that total effort is lower for each of these cases.

Figure 3: Alternative Distributions

We turn to comparing the total effort with maximal discrimination to the total effort with split densities. In order to capture that densities can be split arbitrarily, we assign a share  $a(v) \in (0, 1)$  of the density to  $\hat{F}_A$ , while the remainder,  $1 - a(v)$  is allocated to  $\hat{F}_B$ . In order to compare total effort, we again need to keep track of changes in virtual values and allocation probabilities. We therefore impose some structure on the allocation probabilities. Namely, we construct for the distributions  $\hat{F}$  auxiliary distributions that rank the allocation probabilities and are equivalent in total effort. More precisely, we define by  $\bar{x}_A(v)$  the maximum of the allocation probabilities  $\hat{x}_A(v)$ ,  $\hat{x}_B(v)$  if  $v \geq v^M$  and equivalently, by  $\bar{x}_B(v)$  the maximum of  $\hat{x}_A(v)$ ,  $\hat{x}_B(v)$  if  $v < v^M$ . The corresponding virtual values are denoted by  $\bar{\psi}_i$ . We then compare

$$\begin{aligned} & \int_{v^M}^{\omega} \psi_A^*(v) \bar{x}_A(v) h(v) dv + \int_{\alpha}^{v^M} \psi_B^*(v) \bar{x}_B(v) h(v) dv \\ & > \int_{\alpha}^{\omega} (a(v) \bar{\psi}_A(v) \bar{x}_A(v) + (1 - a(v)) \bar{\psi}_B(v) \bar{x}_B(v)) h(v) dv. \end{aligned} \quad (21)$$

The LHS of (21) presents the lower bound of total effort with maximal discrimination, given by the virtual values of distributions  $F_A^*$  and  $F_B^*$  combined with the allocation probabilities of the auxiliary distributions.<sup>7</sup> The RHS of (21) equals total effort with split densities. The problem can then be reframed as one of signing the following differences:

$$\psi_i(v) \bar{x}_i(v) - a(v) \bar{\psi}_A(v) \bar{x}_A(v) - (1 - a(v)) \bar{\psi}_B(v) \bar{x}_B(v) \quad (22)$$

$$> (\psi_i(v) - a(v) \bar{\psi}_A(v) - (1 - a(v)) \bar{\psi}_B(v)) \bar{x}_i(v), \quad i \in \{A, B\}, \quad (23)$$

where the inequality follows from the definition of the allocation probabilities. We therefore have simplified the problem to a comparison of virtual values. If the difference in virtual values

<sup>7</sup>As in the case of first order stochastic dominance assigning a different allocation probabilities weakly lowers total effort.

is positive for  $A$  and  $B$ , for all  $v$ , then we have shown that total effort is higher under maximal discrimination compared to any split. It turns out that this is straightforward and we obtain that the difference in virtual values is zero for values above the median  $v^M$ , while it is equal to one for values below the median.

This implies that the gain in virtual valuation occurs in the lower half of the value distribution. In the upper half of the value distribution, the information rent is always low, and therefore the exact distributions covering  $H(v)$  are irrelevant. In the bottom half, however, the information rent is high. Recall that the information rent amounts to  $\frac{1-F(v)}{f(v)}$ , which is high if  $F(v)$  and  $f(v)$  are low. Therefore maximal discrimination is optimal as it assigns the highest mass possible to low values, where it is particularly valuable to minimise information rent.

Moreover, it is not optimal to divide the distributions into finer intervals, without splitting densities. As with splitting densities, we construct an auxiliary distributions that allows us to rank allocation probabilities. Again, this simplifies the comparison of total efforts. It boils down to a comparison of virtual values. In contrast to splitting densities, the employer can now reduce the information rent for values above the median, compared to maximal discrimination: there can always be a distribution with sufficiently high mass up to some value  $v$ , such that the information rent is lower at  $v$ . This is countered by a loss in information rent at some other, lower values. However, the gain in information rent for higher values cannot make up for the loss at lower values—as at lower values, the information rent is highest.

As was the case for previous constraints, competition is of secondary importance. It is crucial for the employer to minimise the information rent and he achieves this through maximal discrimination. In particular, he saves on information rent for those workers who value the promotion little and thus discrimination disadvantages them not only as they face lower values, but also as for these values the information rent is reduced. Consequently, an employer who hires two identical workers, will induce differences in how they value the promotion, through creating the appropriate work place culture.

## 4 Discussion and Conclusion

Our analysis highlights that an employer can induce higher effort by introducing a culture with a focus on one worker, creating a bi-modal value distribution for him, while ignoring the other worker. Additionally, the employer finds it beneficial to reallocate value such that one worker displays a high value for the promotion, while the other one ends up with a lower valuation.

In the context of law, banking and management consultancies, culture is often described to be cut-throat, a toxic environment with extremely long work hours. Such a culture is loved by few and disliked by many and matches the bi-modal value distribution that emerges in the value dispersion case. Similarly, in these environments, fit is important. And for some workers, fitting in is more challenging than others as described in a case study by [Padavic, Ely, and Reid \(2020\)](#): they argue that such an environment disproportionately excludes women, as they face both an

expectation to spend time with their family as well as to focus on work, creating a lose-lose situation for them. This reduces their value for a promotion. Our model therefore proposes a novel explanation for why some groups, such as women, fail to raise through the ranks, in line with the empirical evidence.<sup>8</sup>

Our model also sheds light on why minorities, such as women, are not as underrepresented at entry level jobs. In our model, it is optimal to hire workers with the highest value for promotion, independently of their gender or other characteristics. A higher average value results in higher value extraction if the employer is bound by the expected value of the initial distribution. If the employer is constrained by the initial distribution, he prefers workers with distributions with low information rent, that is a narrow distribution. This translates into screening individuals to select those with the highest expected value and low variation. Such a hiring strategy is indeed followed by top law firms, universities and in finance, who prefer graduates from top programmes. Nevertheless, the employer has an incentive to create certain cultures for their entry level employees— a feature contrary to existing theories of discrimination. If there was a distaste toward certain types of employees, they would not even be hired. Further, there is less information about a worker’s ability available at the hiring stage, which should lessen statistical discrimination at the promotion stage compared to the entry level. This pattern indeed emerges in [Bohren, Imas, and Rosenberg \(2019\)](#)’s model of dynamic statistical discrimination and is confirmed through an experiment: statistical discrimination is less important at later career stages. Thus, we propose a novel mechanism of why discrimination arises, which is supported by empirical regularities.

To conclude, we allow the employer to establish the optimal mechanism for the allocation of a promotion and additionally, to design the value for the promotion by implementing a certain workplace culture subject to a constraint. We allow for a large, natural set of constraints, including first and second order stochastic dominance and obtain that introducing inequalities is generally profitable.

We focus throughout on two workers, although it is straightforward to extend the value dispersion setting to multiple workers. Similarly, we speculate that an extension to multiple workers in the value reallocation setting leads to a split support similar to what we find in the case with two workers as it will still be optimal to minimise the information rent.

---

<sup>8</sup>Our explanation for the underrepresentation of women in management positions is complementary to those presented in [Bertrand, Goldin, and Katz \(2010\)](#), [Gayle and Golan \(2011\)](#), [Gneezy, Niederle, and Rustichini \(2003\)](#), [Niederle and Vesterlund \(2007\)](#), [Dohmen and Falk \(2011\)](#), [Erosa, Fuster, Kambourov, and Rogerson \(2017\)](#).

## A Appendix

**Proof of Proposition 1: No Constraints** Note first that it is not possible to obtain a total effort higher than  $\bar{\omega}$ :

$$\mathbb{E}_q [\phi_A(q)y_A(q)] + \mathbb{E}_q [\phi_B(q)y_B(q)] \leq \mathbb{E}_q [v_A(q)y_A(q)] + \mathbb{E}_q [v_B(q)y_B(q)] \quad (24)$$

$$\leq \mathbb{E}_q [\bar{\omega}y_A(q)] + \mathbb{E}_q [\bar{\omega}y_B(q)] \leq \bar{\omega}, \quad (25)$$

where the first inequality follows from  $v(q) \geq \phi(q)$ , the second equality from  $v \leq \bar{\omega}$  and the last inequality from  $E_q [y_A(q)] + E_q [y_B(q)] \leq 1$  where the allocation rule is irrelevant. Therefore, as long as one worker has value  $\bar{\omega}$  and he obtains the promotion, the firm extracts the highest possible total effort. ■

**Proof of Proposition 2: Value Dispersion, 1 Worker** We compare total effort when setting  $F_B^*$  to the total effort the seller would obtain when setting some other distribution  $F_B$  such that  $\mathbb{E}_{v \sim F_b}[v] = \mathbb{E}_{v \sim G}[v]$ . In a quantile setting, for  $\bar{q} = 1 - F_B^*(0)$ , the virtual value for the distribution  $F_B^*$  amounts to

$$\phi_B^*(q) = \begin{cases} \bar{\omega} & \text{if } q < \bar{q} \\ 0 & \text{if } q > \bar{q} \end{cases}. \quad (26)$$

Total effort under distribution  $F_B^*$  is given by

$$\mathbb{E} [\phi_A(q)y_A^*(q)] + \mathbb{E} [\phi_B^*(q)y_B^*(q)], \quad (27)$$

while the effort under the alternative  $F^B$  amounts to

$$\mathbb{E} [\phi_A(q)y_A(q)] + \mathbb{E} [\phi_B(q)y_B(q)]. \quad (28)$$

By optimality, we have that

$$\mathbb{E} [\phi_A(q)y_A^*(q)] + \mathbb{E} [\phi_B^*(q)y_B^*(q)] \geq \mathbb{E} [\phi_A(q)y_A(q)] + \mathbb{E} [\phi_B^*(q)y_B(q)]. \quad (29)$$

Therefore, to prove the result it suffices to establish that

$$\mathbb{E} [\phi_B^*(q)y_B(q)] - \mathbb{E} [\phi_B(q)y_B(q)] \geq 0. \quad (30)$$

For any  $q < \bar{q}$ , it must be that  $\phi_B^*(q) = \bar{\omega} \geq \phi_B(q)$ , since  $\phi_B(q) = v_i(q) + v_i'(q)q \leq v_i(q) \leq \bar{\omega}$ . Instead, for  $q \geq \bar{q}$  and  $y_B(q) > 0$ , it must be that  $\phi_B(q) \geq \phi_B^*(q) = 0$ , since the promotion will only be given to someone with non-negative virtual value. As incentive compatibility requires  $y_B(q)$  to be non-increasing, we have that if

$$\mathbb{E} [\phi_B^*(q) - \phi_B(q)] \geq 0 \quad \Rightarrow \quad \mathbb{E} [(\phi_B^*(q) - \phi_B(q))y_B(q)] \geq 0. \quad (31)$$

By construction, the expected virtual values satisfy

$$\mathbb{E}[\phi_B^*(q)] = \mathbb{E}[v_B^*(q)] = \bar{q}\bar{\omega} = \mathbb{E}[v_A(q)] = \mathbb{E}[v_B(q)]. \quad (32)$$

The result then obtains, because expected virtual value for  $F_B$  satisfies

$$\mathbb{E}[v_B(q)] \geq \mathbb{E}[\phi_B(q)], \quad (33)$$

given that  $\phi_B(q) - v_B(q) = v'_B(q)q \leq 0$  for all  $q > 0$ . This establishes that it is never optimal to select a distribution for  $B$  such that the expected virtual value is below the expected value. However, there are multiple distribution that allow for the expected value to be equal to the expected virtual value,  $\mathbb{E}[v_B(q)] = \mathbb{E}[\phi_B(q)]$ . Note however that is never optimal to allocate mass to more than two values  $v > 0$ . Suppose to the contrary, the firm chose such a distribution. Then, the allocation probability must differ across the different valuations for this to be incentive compatible. Otherwise a worker with a higher valuation would pretend to be a worker with a lower valuation and still obtain the promotion with the same probability. It follows that it is not feasible to extract the entire valuation, yielding the contradiction.

We evaluate the effect of the different distributions that reduce information rent to zero on  $A$ 's effort  $\mathbb{E}[\phi_A(q)y_A(q)]$ . Note that  $A$  only obtains the promotion if  $B$ 's virtual valuation is smaller than  $A$ 's:

$$\mathbb{E}[\phi_A(q)y_A(q)] = \int_{q_A} \phi_A(q_A) (1 - \hat{q}_B(v_B = \phi_A(q_A))) dq_A, \quad (34)$$

where  $\hat{q}_B(v_B = \phi_A(q_A))$  is the highest value of  $q_B$  for which  $v_B \geq \phi_A(q_A)$ . Given that  $B$ 's distribution only has positive mass at one positive value, it follows that  $A$  either obtains the promotion with certainty or not. Clearly, equation (34) is maximised for  $q_B$  approaching zero for any  $q_A$ , for which  $\phi_A(q_A) \geq 0$ . For  $\phi_A(q_A) < 0$ , the allocation probability becomes 0. This implies that the maximal effort is bounded above by

$$\mathbb{E}_G[v] + (1 - \hat{q}_B)\mathbb{E}[\phi_A(q)] < \mathbb{E}_G[v] + \mathbb{E}[\phi_A(q)] \quad (35)$$

There are different possible distributions for  $B$  that can potentially minimise the probability that  $B$  obtains the promotion. We first show that allocating mass at zero and  $\bar{\omega}$  can indeed lead for  $q_B$  to be arbitrary small, a feature other allocations do not possess, making it the optimal distribution.

1. *Mass at  $\bar{\omega}$  and 0* While it is never possible to set the probability that  $B$  obtains the promotion to zero for all positive virtual values of  $A$ ,  $B$ 's probability can be made arbitrarily small, by choosing  $\bar{\omega}$  and allowing for this to become arbitrarily large. This implies that  $q_B = \bar{q}$  becomes arbitrarily small. More formally,

$$F_B(0) \int_{t_A}^{\omega_A} \psi_A(v) dF_A(v), \quad (36)$$

where  $t_A$  addresses the exclusion restriction. As  $\int_{t_A}^{\omega_A} \psi_A(v) dF_A(v)$  is independent of  $\omega_B$ , the effect is purely driven by  $F_B(0)$ . As  $\omega_B$  increases,  $F_B(0)$  increases:

$$\frac{\partial((1-F(0))\omega_B)}{\partial\omega_B} = (1-F(0)) + \omega_B \frac{\partial(1-F(0))}{\partial\omega_B} = 0 \quad (37)$$

We can rewrite this as  $(1-F(0))\omega_B = \mathbb{E}[v_A]$  or equivalently,  $(1-F(0)) = \frac{\mathbb{E}[v_A]}{\omega_B}$

$$\frac{\mathbb{E}[v_A]}{\omega_B} = \omega_B \frac{\partial F(0)}{\partial\omega_B} \quad (38)$$

$$\Leftrightarrow \frac{\partial F(0)}{\partial\omega_B} = \frac{\mathbb{E}[v_A]}{\omega_B^2} > 0 \quad (39)$$

And therefore, the expected effort from  $A$  increases if  $\omega_B$  increases. By setting  $\bar{\omega}$  sufficiently large, there always exists a  $\bar{q}$ , such that  $\bar{q} < \epsilon$ .

2. *Allocate mass 1 to  $v_B = \mathbb{E}_{v \sim G}[v]$* : Suppose first that  $G$  is regular, which implies no discontinuities. In this case, allocating mass at the mean always affects  $A$ 's promotion probability as  $\phi_A(0) = v_A(0) > \mathbb{E}_{v \sim G}[v]$  and  $\phi_A(q)$  is strictly decreasing, such that there is a region for which  $\phi_A(q) < \mathbb{E}_{v \sim G}[v]$ . To see this note that there exists  $v_A(q) \equiv v(q) < \mathbb{E}_{v \sim G}[v]$  and  $\phi_A(q) < v_A(q)$ . Therefore, the effect on the promotion probability is not arbitrarily small and so such an adjustment cannot be optimal.

Suppose next  $G$  has a discontinuity. Denote by  $q_A^M$  the quantile such that  $\phi_A(q) > \mathbb{E}_{v \sim G}[v]$  for  $q \in [0, q_A^M)$  and  $\phi_A(q) \leq 0$  for  $q \in [q_A^M, 1]$ . Total effort is then given by

$$q_A^M \mathbb{E}[\phi_A[q] | q < q_A^M] + (1 - q_A^M) \mathbb{E}_{v \sim G}[v] \quad (40)$$

Note that  $\mathbb{E}[\phi_A[q] | q < q_A^M] \leq \mathbb{E}[v_A[q] | q < q_A^M]$ . Additionally,  $q_A^M \mathbb{E}[v_A[q] | q < q_A^M] \leq \mathbb{E}_{v \sim G}[v]$  as  $\mathbb{E}_{v \sim G}[v] = q_A^M \mathbb{E}[v_A[q] | q < q_A^M] + (1 - q_A^M) \mathbb{E}[v_A[q] | q \geq q_A^M]$ . This implies that

$$q_A^M \mathbb{E}[\phi_A[q] | q < q_A^M] + (1 - q_A^M) \mathbb{E}_{v \sim G}[v] \leq \mathbb{E}_{v \sim G}[v] + (1 - q_A^M) \mathbb{E}_{v \sim G}[v] \quad (41)$$

This condition only holds with equality if  $A$ 's distribution is such that mass  $\bar{q}$  is allocated to  $\bar{\omega}$ . Thus, generically, this condition holds with inequality and allocating mass at the mean does not yield optimal total effort. ■

**Proof of Corollary 2.1: Second Order Stochastic Dominance** We show that  $F_B^*$  is second stochastically dominated by  $F_A = G$ . First note that if  $F_B^* = F_A$ , then  $F_B^*$  is SOSD by  $F_A$  by definition. If both distributions are unequal, it holds that

$$\Delta(v) = F_A(v) - F_B^*(v) < 0 \quad (42)$$

for  $v \in [0, \bar{v})$ ,  $\bar{v} \in [\alpha_A, \omega_A]$ . It follows that

$$\int_0^v \Delta(t)dt = \int_0^v F_A(t)dt - \int_0^v F_B^*(t)dt < 0; \quad (43)$$

for  $v \in [0, \bar{v})$ . Moreover,

$$\int_0^{\bar{\omega}} \Delta(t)dt = [t(F_A(t) - F_B^*(t))]_0^{\bar{\omega}} - \int_0^{\bar{\omega}} t d(F_A(t) - F_B^*(t)) = 0. \quad (44)$$

This implies that  $\int_0^{\bar{\omega}} \Delta(t)dt > 0$ . To establish second order stochastic dominance, it then remains to be shown that  $F_A(v) - F_B^*(v)$  is non-decreasing. This holds as  $F_A$  is non-decreasing and  $F_B^*$  is constant up until  $\bar{\omega}$ . Therefore for any  $v \leq \bar{\omega}$  we established that  $A$ 's distribution SOSDs  $B$ 's distribution. ■

**Proof of Proposition 3: FOSD** Suppose by contradiction that the firm found it optimal to set  $F_B \neq F_A$ , which implies that  $F_B(v) > F_A(v)$  for some  $v$ . We show that in this case, there exists a profitable deviation to a distribution  $\hat{F}_B$ , such that  $F_B(v) \geq \hat{F}_B(v)$  with strict inequality for some  $v$  and  $\hat{F}_B(v) \geq F_A(v)$ .

The change from  $F_B$  to  $\hat{F}_B$  has two effects: (i) it affects the virtual valuation of worker  $B$  and (ii) it affects the optimal allocation rule for the promotion. We begin by keeping the allocation rule fixed and show that a change from  $F_B$  to  $\hat{F}_B$  increases total effort under the same allocation rule. Recall that optimal total effort is given by

$$\mathbb{E}[\phi_A(q)y_A(q)] + \mathbb{E}[\phi_B(q)y_B(q)] = \int_0^1 \phi_A(q)y_A(q)dq + \int_0^1 \phi_B(q)y_B(q)dq. \quad (45)$$

As the allocation rule is unchanged,  $\mathbb{E}[\phi_A(q)y_A(q)]$  is not affected, and we only need to establish that

$$\mathbb{E}[\hat{\phi}_B(q)y_B(q)] \geq \mathbb{E}[\phi_B(q)y_B(q)] \Leftrightarrow \int_0^1 (\hat{\phi}_B(q) - \phi_B(q)) y_B(q)dq \geq 0. \quad (46)$$

Integration by parts implies that

$$\mathbb{E}[\phi_B(q)y_B(q)] = \alpha_B y_B(1) - \mathbb{E}[qv_B(q)y_B'(q)]. \quad (47)$$

But if so we get that

$$\int_0^1 (\hat{\phi}_B(q) - \phi_B(q)) y_B(q)dq = (\hat{\alpha}_B - \alpha_B)y_B(1) + \int_0^1 (qv_B(q) - q\hat{v}_B(q)) dy_B(q). \quad (48)$$

As  $\hat{F}_B$  first order stochastically dominates  $F_B$ , we know that  $\hat{\alpha}_B \geq \alpha_B$  and that  $v_B(q) \leq \hat{v}_B(q)$ . As the allocation probability is decreasing in  $q$  by incentive compatibility,  $dy_B(q) \leq 0$ , it follows

that

$$\mathbb{E}[\phi_A(q)y_A(q)] + \mathbb{E}[\hat{\phi}_B(q)y_B(q)] \geq \mathbb{E}[\phi_A(q)y_A(q)] + \mathbb{E}[\phi_B(q)y_B(q)]. \quad (49)$$

Moreover, if the firm was allowed to set the allocation rule  $\hat{y}(q)$  optimally, total effort further increases

$$\mathbb{E}[\phi_A(q)\hat{y}_A(q)] + \mathbb{E}[\hat{\phi}_B(q)\hat{y}_B(q)] \geq \mathbb{E}[\phi_A(q)y_A(q)] + \mathbb{E}[\hat{\phi}_B(q)y_B(q)], \quad (50)$$

or else the employer would prefer to leave allocation rule unchanged. ■

**Proof of Proposition 4: Reallocating Value, Fixed Distribution** We can restrict attention to regular  $G(v)$ . If this was not the case and the employer chooses a  $\hat{G}(v)$  that is not regular, then we can consider an ironed function  $G(v)$ , which yields the same total effort, see [Hartline \(2013\)](#), Theorem 3.14, p.78. This then yields a distribution  $H(v) = 2G(v)$ , which is also regular.

We want to show that the adjusted distributions, which lead to maximal discrimination

$$F_B^*(v) = H(v) \quad \text{if } v \in [\alpha, v^M) \quad (51)$$

$$F_A^*(v) = H(v) - 1 \quad \text{if } v \in [v^M, \omega], \quad (52)$$

maximise total effort. In order to simplify notation, we drop the star to indicate the optimal adjustment and simply refer to the optimal distributions by  $F_A(v)$  and  $F_B(v)$ . Instead, we mark any deviation.

We proceed by first showing that  $F_A(v)$  and  $F_B(v)$  yield higher effort than any other distributions that split the density  $h(v)$  at each  $v$ . In a second step, we prove that  $F_A(v)$  and  $F_B(v)$  lead to higher total effort than any other distribution which allocates density  $h(v)$  at each  $v$  to either  $A$ 's or  $B$ 's distribution. Last, we show that  $F_A(v)$  and  $F_B(v)$  yield a higher total effort than any two distributions that combine splitting densities and assigning densities to one distribution.

**Splitting Densities** We want to compare total effort with maximal discrimination to total effort with split densities, where  $\hat{f}_i(v) > 0$ ,  $i \in \{A, B\}$  for each  $v \in [\alpha, \omega]$ . Denote by  $a(v)$  the share of the density  $h(v)$  assigned to  $A$  and by  $1 - a(v)$  the share assigned to  $B$ . We want to show that

$$\int_{v^M}^{\omega} \psi_A(v)x_A(v)h(v)dv + \int_{\alpha}^{v^M} \psi_B(v)x_B(v)h(v)dv \quad (53)$$

$$\geq \int_{\alpha}^{\omega} \hat{\psi}_A(v)\hat{x}_A(v)a(v)h(v)dv + \int_{\alpha}^{\omega} \hat{\psi}_B(v)\hat{x}_B(v)(1 - a(v))h(v)dv \quad (54)$$

Define

$$\bar{x}_A(v) = \begin{cases} \hat{x}_A(v) & \text{if } \hat{x}_A(v) \geq \hat{x}_B(v), v \geq v^M \\ \hat{x}_B(v) & \text{if } \hat{x}_A(v) < \hat{x}_B(v), v \geq v^M \\ \hat{x}_A(v) & \text{if } \hat{x}_A(v) < \hat{x}_B(v), v < v^M \\ \hat{x}_B(v) & \text{if } \hat{x}_A(v) > \hat{x}_B(v), v < v^M \end{cases} \quad (55)$$

Define  $\bar{x}_B(v)$  accordingly. Then,

$$\int_{\alpha}^{\omega} \hat{\psi}_A(v) \hat{x}_A(v) a(v) h(v) dv + \int_{\alpha}^{\omega} \hat{\psi}_B(v) \hat{x}_B(v) (1 - a(v)) h(v) dv \quad (56)$$

$$= \int_{\alpha}^{\omega} \bar{\psi}_A(v) \bar{x}_A(v) \bar{a}(v) h(v) dv + \int_{\alpha}^{\omega} \bar{\psi}_B(v) \bar{x}_B(v) (1 - \bar{a}(v)) h(v) dv \quad (57)$$

As usual, it is sufficient to show that

$$\int_{v^M}^{\omega} \psi_A(v) \bar{x}_A(v) h(v) dv + \int_{\alpha}^{v^M} \psi_B(v) \bar{x}_B(v) h(v) dv \quad (58)$$

$$\geq \int_{\alpha}^{\omega} \bar{\psi}_A(v) \bar{x}_A(v) \bar{a}(v) h(v) dv + \int_{\alpha}^{\omega} \bar{\psi}_B(v) \bar{x}_B(v) (1 - \bar{a}(v)) h(v) dv \quad (59)$$

This is equivalent to

$$\underbrace{\int_{v^M}^{\omega} ((\psi_A(v) - \bar{\psi}_A(v) \bar{a}(v)) \bar{x}_A(v) - \bar{\psi}_B(v) \bar{x}_B(v) (1 - \bar{a}(v))) h(v) dv}_{\text{Part 1}} \quad (60)$$

$$+ \underbrace{\int_{\alpha}^{v^M} ((\psi_B(v) - \bar{\psi}_B(v) (1 - \bar{a}(v))) \bar{x}_B(v) - \bar{\psi}_A(v) \bar{x}_A(v) \bar{a}(v)) h(v) dv}_{\text{Part 2}} > 0 \quad (61)$$

We discuss the two parts in turn.

**Part 1** Note first that

$$\int_{v^M}^{\omega} ((\psi_A(v) - \bar{\psi}_A(v) \bar{a}(v)) \bar{x}_A(v) - \bar{\psi}_B(v) \bar{x}_B(v) (1 - \bar{a}(v))) h(v) dv \quad (62)$$

$$> \int_{v^M}^{\omega} (\psi_A(v) - \bar{\psi}_A(v) \bar{a}(v) - \bar{\psi}_B(v) (1 - \bar{a}(v))) \bar{x}_A(v) h(v) dv \quad (63)$$

Then,

$$\psi_A(v) - \bar{\psi}_A(v) \bar{a}(v) - \bar{\psi}_B(v) (1 - \bar{a}(v)) \quad (64)$$

$$= v - \frac{1 - F_A(v)}{h(v)} - \bar{a}(v) \left( v - \frac{1 - \bar{F}_A(v)}{\bar{a}(v) h(v)} \right) - (1 - \bar{a}(v)) \left( v - \frac{1 - \bar{F}_B(v)}{(1 - \bar{a}(v)) h(v)} \right) \quad (65)$$

$$= -\frac{1 - F_A(v)}{h(v)} + \frac{1 - \bar{F}_A(v)}{h(v)} + \frac{1 - \bar{F}_B(v)}{h(v)} \quad (66)$$

$$= \frac{1}{h(v)} (\bar{q}_A(v) + \bar{q}_B(v) - q_A(v)) \quad (67)$$

Note that for all  $v$ ,

$$\bar{q}_A(v) + \bar{q}_B(v) = \hat{q}_A(v) + \hat{q}_B(v) = 1 - \hat{F}_A(v) + 1 - \hat{F}_B(v) = 2 - \hat{F}_A(v) - \hat{F}_B(v) \quad (68)$$

By assumption,  $\hat{F}_A(v) + \hat{F}_B(v) = H(v)$ , therefore

$$\hat{q}_A(v) + \hat{q}_B(v) = 2 - H(v) = 1 - F_A(v) = q_A(v) \quad (69)$$

where the second equality follows from  $F_A(v) = H(v) - 1$ . Therefore,

$$\bar{q}_A(v) + \bar{q}_B(v) - q_A(v) = 0 \quad (70)$$

for all  $v$ . This implies the first part integrates up to zero.

**Part 2** As in Part 1,

$$\int_{\alpha}^{v^M} ((\psi_B(v) - \bar{\psi}_B(v)(1 - \bar{a}(v))) \bar{x}_A(v) - \bar{\psi}_A(v) \bar{x}_A(v) \bar{a}(v)) h(v) dv \quad (71)$$

$$> \int_{\alpha}^{v^M} (\psi_B(v) - \bar{\psi}_A(v) \bar{a}(v) - \bar{\psi}_B(v)(1 - \bar{a}(v))) \bar{x}_B(v) h(v) dv \quad (72)$$

We can simplify

$$\psi_B(v) - \bar{\psi}_A(v) \bar{a}(v) - \bar{\psi}_B(v)(1 - \bar{a}(v)) \quad (73)$$

$$= \frac{1}{h(v)} (\bar{q}_A(v) + \bar{q}_B(v) - q_B(v)) \quad (74)$$

Note that

$$\bar{q}_A(v) + \bar{q}_B(v) = \hat{q}_A(v) + \hat{q}_B(v) = 2 - H(v) = 1 + 1 - F_B(v) = 1 + q_B(v) \quad (75)$$

We can write

$$\int_{\alpha}^{v^M} (\psi_B(v) - \bar{\psi}_A(v) \bar{a}(v) - \bar{\psi}_B(v)(1 - \bar{a}(v))) \bar{x}_B(v) h(v) dv = \int_{\alpha}^{v^M} \bar{x}_B(v) dv \geq 0 \quad (76)$$

This establishes that splitting a density can never be optimal if there is no exclusion. It is immediate that the result carries over to the case with exclusion as the cut off value under maximal discrimination is weakly higher than the cutoff under any other two distributions.

**Disjoint Support** Having shown that there do not exist two distributions that split the densities and yield a higher total effort, we turn to other distributions which assign each density to one distribution. This implies that the support of at least one distribution is disjoint. We restrict attention to alternative distributions with  $\hat{v}_B \in [\alpha, t_1] \cup [t_2, t_3]$  and  $\hat{v}_A \in [t_1, t_2] \cup [t_3, \omega]$ , with  $\alpha < t_1 < t_2 < t_3 \leq \omega$ . If these distributions do not yield higher total effort than maximal

discrimination, then splitting the distribution further cannot be optimal either. Note that  $t_1 < v^M < t_3$ .

To deal with the disjoint support we analyse the problem in the value-quantile space. Recall that total effort in the quantile space is given by

$$\int_q \phi_A(q)y_A(q)dq + \phi_B(q)y_B(q)dq \quad (77)$$

Integrating each component by parts yields

$$v_i(q)qy_i(q)\Big|_0^1 + \int_q v_i(q)(-y_i'(q))dq = v_i(1)y_i(1) + \int_q v_i(q)(-y_i'(q))dq \quad (78)$$

Flipping this to a  $v - q$ - space yields

$$\alpha_A x_A(\alpha_A) + \int_v v q_A(v) x'_A(v) dv + \alpha_B x_B(\alpha_B) + \int_v v q_B(v) x'_B(v) dv, \quad (79)$$

where  $v_i \in [\alpha_i, \omega_i]$ .

We consider three distinct cases:

1. both distributions with disjoint support, cutoff  $t_2$  below  $v^M$ ,  $t_2 \leq v^M$
2. both distributions with disjoint support, cutoff  $t_2$  above  $v^M$ ,  $t_2 > v^M$
3. one distribution with disjoint support:  $\hat{v}_B \in [\alpha, t_1] \cup [t_2, \omega]$  and  $\hat{v}_A \in [t_1, t_2]$

We relabel  $\hat{x}_i(v)$ ,  $\hat{q}_i(v)$  as  $\tilde{x}_A(v)$ ,  $\tilde{q}_A(v)$  if  $v > v^M$  and as  $\tilde{x}_B(v)$ ,  $\tilde{q}_B(v)$  if  $v < v^M$ . Then, it is sufficient to show that

$$v^M \tilde{x}_A(v^M) + \int_{v^M}^{\omega} q_A(v) \tilde{x}'_A(v) v dv + \int_{\alpha}^{v^M} q_B(v) \tilde{x}'_B(v) v dv \quad (80)$$

$$> t_1 \tilde{x}_B(t_1) + \int_{v^M}^{\omega} \tilde{q}_A(v) \tilde{x}'_A(v) v dv + \int_{\alpha}^{v^M} \tilde{q}_B(v) \tilde{x}'_B(v) v dv \quad (81)$$

*Disjoint Support for  $\hat{F}_A, \hat{F}_B$ :  $t_2 \leq v^M$*  In this case inequality (80) can be amended to

$$v^M \tilde{x}_A(v^M) + \int_{v^M}^{t_3} q_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} q_B(v) \tilde{x}'_B(v) v dv \quad (82)$$

$$> t_1 \tilde{x}_B(t_1) + \int_{v^M}^{t_3} \tilde{q}_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} \tilde{q}_B(v) \tilde{x}'_B(v) v dv, \quad (83)$$

as the distributions are identical below  $t_1$  and above  $t_3$ . Note that  $\tilde{q}_A(v) = \hat{q}_B(v)$  for  $v \in [v^M, t_3]$ .

Taking the difference yields

$$\int_{v^M}^{t_3} (q_A(v) - \hat{q}_B(v)) \tilde{x}'_A(v) v dv \quad (84)$$

where

$$q_A(v) = 2 - H(v) \quad (85)$$

while

$$\hat{q}_B(v) = 1 - \hat{F}_B = 1 - (H(v) - H(t_2) + H(t_1)) \quad (86)$$

Then, for a given  $v \in [v^M, t_3]$

$$q_A(v) - \hat{q}_B(v) = 1 - H(v) + (H(v) - H(t_2) + H(t_1)) = 1 - H(t_2) + H(t_1) > 0 \quad (87)$$

implying that the difference is constant. Expression (84) then becomes:

$$(1 - H(t_2) + H(t_1)) \int_{v^M}^{t_3} \tilde{x}'_A(v) v dv \quad (88)$$

We then turn to

$$\int_{t_1}^{v^M} (q_B(v) - \tilde{q}_B(v)) \tilde{x}'_B(v) v dv \quad (89)$$

Between  $t_2$  and  $v^M$ ,  $\tilde{q}_B(v) = \hat{q}_B(v)$ :

$$q_B(v) - \hat{q}_B(v) = 1 - H(v) - (1 - (H(v) - H(t_2) + H(t_1))) \quad (90)$$

$$= 1 - H(v) - 1 + (H(v) - H(t_2) + H(t_1)) = -(H(t_2) - H(t_1)) < 0 \quad (91)$$

which is again constant. For  $v \in [t_1, t_2]$ , this difference is given by

$$q_B(v) - \hat{q}_A(v) = 1 - H(v) - (1 - (H(v) - H(t_1))) \quad (92)$$

$$= -H(v) + (H(v) - H(t_1)) = -H(t_1) \quad (93)$$

Expression (89) is then equivalent to

$$\int_{t_1}^{v^M} (q_B(v) - \tilde{q}_B(v)) \tilde{x}'_B(v) v dv = -(H(t_2) - H(t_1)) \int_{t_2}^{v^M} \tilde{x}'_B(v) dv - H(t_1) \int_{t_1}^{t_2} \tilde{x}'_B(v) dv \quad (94)$$

Collecting all terms leads to the following comparison

$$v^M \tilde{x}_A(v^M) + (1 - H(t_2) + H(t_1)) \int_{v^M}^{t_3} \tilde{x}'_A(v) v dv - (H(t_2) - H(t_1)) \int_{t_2}^{v^M} \tilde{x}'_B(v) v dv \quad (95)$$

$$- H(t_1) \int_{t_1}^{t_2} \tilde{x}'_B(v) v dv > t_1 \tilde{x}_B(t_1) \quad (96)$$

Rearranging yields

$$v^M \tilde{x}_A(v^M) + \int_{v^M}^{t_3} \tilde{x}'_A(v) v dv - (H(t_2) - H(t_1)) \int_{t_2}^{t_3} \tilde{x}'_{A \setminus B}(v) v dv - H(t_1) \int_{t_1}^{t_2} \tilde{x}'_B(v) v dv > t_1 \tilde{x}_B(t_1) \quad (97)$$

As  $H(t_1), H(t_2) - H(t_1) < 1$ , it suffices to show that

$$t_3 \tilde{x}_A(t_3) - \int_{v^M}^{t_3} \tilde{x}_A(v) dv - (t_3 \tilde{x}_A(t_3) - t_1 \tilde{x}_B(t_1)) + \int_{t_1}^{t_3} \tilde{x}(v) dv > \tilde{x}_B(t_1) t_1 \quad (98)$$

$$\Leftrightarrow \int_{t_1}^{v^M} \tilde{x}_B(v) dv > 0, \quad (99)$$

which always holds and establishes that any other disjoint distributions do not yield a higher total effort.

*Disjoint Support for  $\hat{F}_A, \hat{F}_B$ :*  $t_2 > v^M$  By the same logic as in the previous case, it is sufficient to show

$$v^M \tilde{x}_A(v^M) + \int_{v^M}^{t_3} q_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} q_B(v) \tilde{x}'_B(v) v dv \quad (100)$$

$$> t_1 \tilde{x}_B(t_1) + \int_{v^M}^{t_3} \tilde{q}_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} \tilde{q}_B(v) \tilde{x}'_B(v) v dv \quad (101)$$

As before, with a different integration bound below

$$\int_{t_2}^{t_3} q_A(v) - \hat{q}_B(v) \tilde{x}'_A(v) v dv = (1 - H(t_2) + H(t_1)) \int_{t_2}^{t_3} \tilde{x}'_A(v) v dv \quad (102)$$

We turn to

$$\int_{v^M}^{t_2} (q_A(v) - \hat{q}_A(v)) \tilde{x}'_A(v) v dv \quad (103)$$

$$q_A(v) - \hat{q}_A(v) = 2 - H(v) - (1 - (H(v) - H(t_1))) \quad (104)$$

$$= 1 - H(v) + (H(v) - H(t_1)) = 1 - H(t_1) \quad (105)$$

Then,

$$\int_{v^M}^{t_2} (q_A(v) - \hat{q}_A(v)) \tilde{x}'_A(v) v dv = (1 - H(t_1)) \int_{v^M}^{t_2} \tilde{x}'_A(v) v dv \quad (106)$$

Last,

$$\int_{t_1}^{v^M} (q_B(v) - \hat{q}_A(v)) \tilde{x}'_A(v) v dv = -H(t_1) \int_{t_1}^{v^M} \tilde{x}'_B(v) v dv \quad (107)$$

Collecting terms yields

$$v^M \tilde{x}_A(v^M) + (1 - H(t_2) + H(t_1)) \int_{t_2}^{t_3} \tilde{x}'_A(v) v dv + (1 - H(t_1)) \int_{v^M}^{t_2} \tilde{x}'_A(v) v dv \quad (108)$$

$$- H(t_1) \int_{t_1}^{v^M} \tilde{x}'_B(v) v dv > t_1 \tilde{x}_B(t_1) \quad (109)$$

As before it is sufficient to show that

$$t_3 \tilde{x}_A(t_3) - \int_{v^M}^{t_3} \tilde{x}_A(v) dv - (t_3 \tilde{x}_A(t_3) - t_1 \tilde{x}_B(t_1)) + \int_{t_1}^{t_3} \tilde{x}_{A \setminus B}(v) dv > \tilde{x}_B(t_1) t_1 \quad (110)$$

$$\Leftrightarrow \int_{t_1}^{v^M} \tilde{x}_B(v) dv > 0 \quad (111)$$

This establishes that also in this case, maximal discrimination yields the highest effort.

*Disjoint Support for  $\hat{F}_B$ :  $t_2 > v^M$*  In this case, it is sufficient to show

$$v^M \tilde{x}_A(v^M) + \int_{v^M}^{t_2} q_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} q_B(v) \tilde{x}'_B(v) v dv \quad (112)$$

$$> t_1 \tilde{x}_B(t_1) + \int_{v^M}^{t_2} \tilde{q}_A(v) \tilde{x}'_A(v) v dv + \int_{t_1}^{v^M} \tilde{q}_B(v) \tilde{x}'_B(v) v dv \quad (113)$$

As before,

$$\int_{v^M}^{t_2} q_A(v) - \hat{q}_A(v) \tilde{x}'_A(v) v dv = (1 - H(t_1)) \int_{v^M}^{t_2} \tilde{x}'_A(v) v dv \quad (114)$$

$$\int_{t_1}^{v^M} q_B(v) - \hat{q}_B(v) \tilde{x}'_B(v) v dv = -H(t_1) \int_{t_1}^{v^M} \tilde{x}'_B(v) v dv \quad (115)$$

Following the same steps as before, establishes that maximal discrimination yields higher total effort, than this adjustment.

**Mixing Split Densities and Disjoint Supports** It follows that there cannot be any other two distributions that combine mixing split densities and disjoint supports that yield higher total effort compared to maximal discrimination. We can always treat subsets of the distribution as the entire distribution. This just requires an adjustment of the mass in a certain subset. Then we can perform the same analysis as we did for a subset, which yields lower total effort for this subset by the same logic as above.

Therefore, we have established that maximal discrimination is optimal and yields highest total effort among all possible distributions. ■
